Protein Structural Alignment using τ-Equivalence Method

Based on Subbarao & Haneef (1991)

---

1. Introduction

In structural biology, the function of a protein is primarily determined by its three-dimensional structure rather than its amino acid sequence. As a result, structural comparison of proteins is essential for understanding evolutionary relationships and functional similarities.

The method proposed by Subbarao and Haneef (1991) introduces an alternative approach to structural alignment based on **topological equivalence**. Unlike traditional methods that rely on direct spatial superposition, this approach first analyses the internal geometric environment of residues and then determines structural similarity. A graph consists of vertices (representing Cα atoms) connected by edges (representing interatomic distances in the 5–8 Å range). Cα atoms are used as representative points for each residue because they define the backbone geometry of the protein while avoiding side-chain flexibility

---

2. Concept of τ and δ Equivalence

The methodology operates in two main stages:

2.1 τ-equivalence (Topological equivalence)

Two residues are τ-equivalent if for every other already-equivalent pair (a, b), the difference in their interatomic distances satisfies $|d(i,a) - d(j,b)| < \tau$. Critically, this requires **no prior superposition** of the structures

In simple terms, τ-equivalence identifies residues that occupy similar structural environments, independent of their absolute spatial positions.

2.2 δ-equivalence (Spatial equivalence)

After identifying τ-equivalent residues, the structures are superimposed. Only those residue pairs that remain consistent after spatial alignment are retained as δ-equivalent.

Thus, δ-equivalence represents a refined and geometrically valid subset of τ-equivalences.

2.3 RMSD (Root Mean Square Deviation)

RMSD measures the average distance between aligned residues after superposition. It is an indicator of alignment quality, where lower values correspond to better structural similarity.

---

3. Methodology

The structural comparison of proteins was carried out by implementing the τ-equivalence algorithm in a Python script executed using Visual Studio Code. Protein structures were obtained in PDB format and

parsed to extract the coordinates of residues from selected chains. For each pair of proteins, the internal distance relationships between residues were computed to identify τ-equivalent pairs under varying distance thresholds (τ values ranging from 0.5 Å to 3.0 Å). These initial matches were then refined through spatial superposition to determine δ-equivalences, ensuring geometrical consistency. The quality of alignment was evaluated using Root Mean Square Deviation (RMSD). The script systematically generated results tables for each protein pair, and the outputs were recorded and verified through screenshots to document the computational procedure and results. Neighbor residues were defined within a distance range (typically 5–8 Å) to construct the local structural environment.

4. Dataset and Biological Significance

PDB ID	Molecule Name	Description
3DFR	Dihydrofolate Reductase (DHFR) – *Lactobacillus casei*	Enzyme involved in folate metabolism; used as a model for closely related homologs
4DFR	Dihydrofolate Reductase (DHFR) – *Escherichia coli*	Homolog of DHFR with high structural similarity to 3DFR
2HHB	Hemoglobin (α-chain) – *Homo sapiens*	Oxygen transport protein; part of tetrameric hemoglobin
1MBD	Myoglobin – *Physeter catodon* (Sperm whale)	Oxygen storage protein with globin fold
2LZM	T4 Lysozyme – Bacteriophage T4	Enzyme that breaks bacterial cell walls; structurally distinct lysozyme
1LYZ	Hen Egg White Lysozyme – *Gallus gallus*	Well-studied lysozyme enzyme with different fold than T4 lysozyme
3CYT	Cytochrome c – *Equus caballus* (Horse)	Electron transport protein involved in respiration
3C2C	Cytochrome c2 – *Rhodobacter capsulatus*	Homologous electron transport protein
2AZA	Azurin – *Pseudomonas aeruginosa*	Blue copper protein involved in electron transfer
1PCY	Plastocyanin – *Populus nigra* (Poplar)	Copper-containing electron transfer protein in photosynthesis

The selected protein pairs represent a range of evolutionary and structural relationships:

Protein Pair	Biological Relationship	Purpose
L. casei DHFR vs E. coli DHFR	Close homologs	To examine strong structural similarity
Hemoglobin-α vs Myoglobin	Divergent homologs	To identify conserved structural folds
T4 Lysozyme vs Hen Lysozyme	Functional analogs	To test absence of structural similarity
Cytochrome-c vs Cytochrome-c2	Evolutionary variants	To analyse stability under varying conditions
Azurin vs Plastocyanin	Blue copper proteins	To examine moderate structural similarity

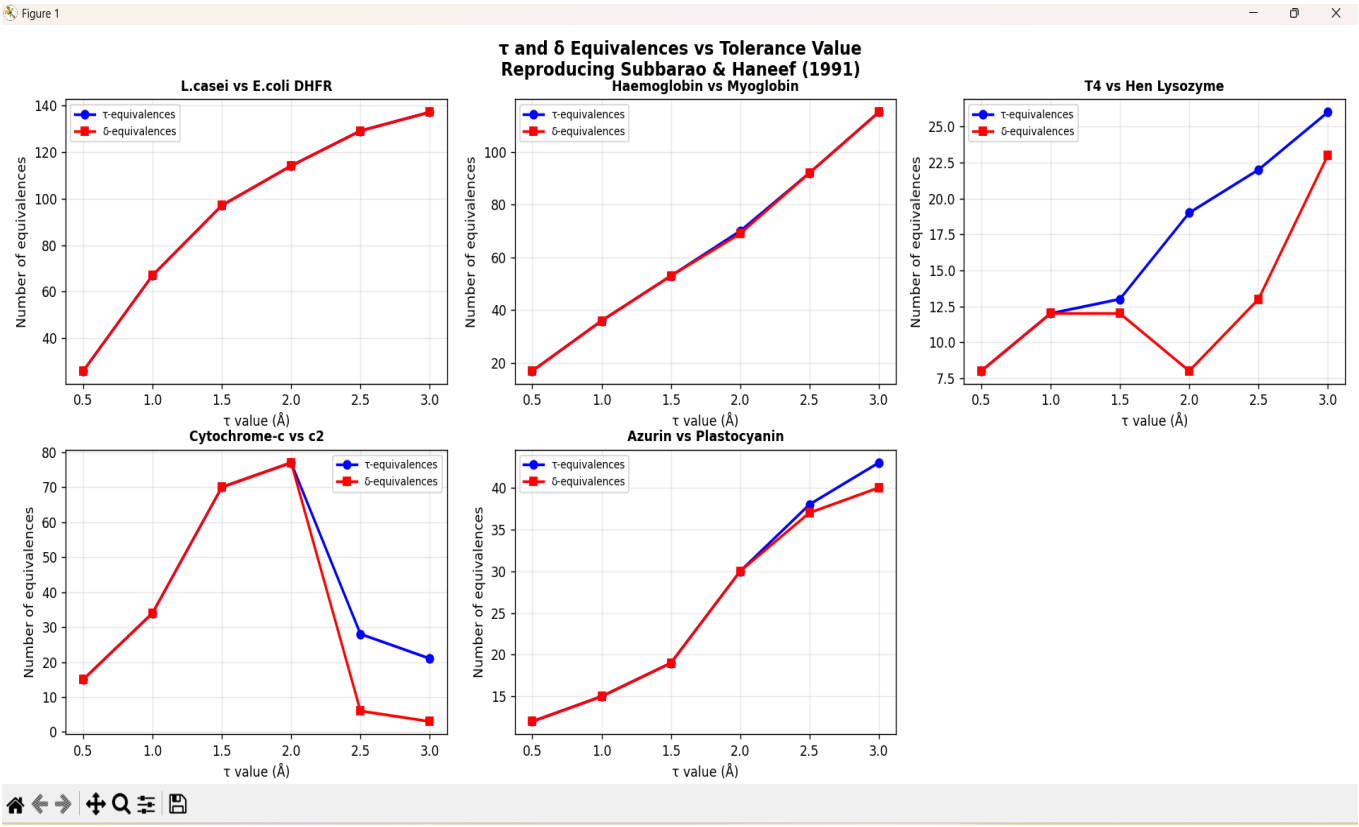
5. Results Summary (τ = 1.5 Å)

Protein Pair	τ-equivalences	δ-equivalences	RMSD (Å)	Interpretation
DHFR vs DHFR	97	97	0.72	Strong structural similarity
Hemoglobin vs Myoglobin	53	53	0.74	Conserved globin fold
Lysozyme vs Lysozyme	13	12	1.92	Weak similarity
Cytochrome vs Cytochrome	70	70	0.72	Strong conserved core
Azurin vs Plastocyanin	19	19	0.96	Moderate similarity



6. Detailed Analysis of Results

6.1 DHFR vs DHFR (Close Homologs)

A high number of equivalences and low RMSD indicate strong structural similarity. The alignment captures most of the protein backbone, consistent with expectations for closely related homologs.

6.2 Hemoglobin vs Myoglobin (divergent homologs)

Despite low sequence identity, a significant number of equivalences with low RMSD confirms the presence of a conserved structural fold. This highlights the principle that structural conservation can persist even when sequence similarity is low.

6.3 Lysozyme vs Lysozyme (Negative Control)

The low number of equivalences and relatively high RMSD indicate poor structural alignment. This suggests that although both proteins share a similar function, their structural architectures are fundamentally different.

6.4 Cytochrome-c vs Cytochrome-c2

A stable alignment is observed at lower τ values, with a high number of equivalences and low RMSD. However, at higher τ values, a sudden decrease in equivalences and a sharp increase in RMSD are observed. This reflects instability in alignment due to inclusion of incorrect matches at higher tolerance levels. This

demonstrates that τ must be selected carefully the optimal value for this pair is 1.5–2.0 Å. Beyond this, the seed expansion accepts geometrically plausible but biologically incorrect distance patterns, causing the entire superposition to fail.

This phenomenon demonstrates that excessively large τ values introduce false-positive matches, leading to breakdown of meaningful structural alignment.

6.5 Azurin vs Plastocyanin

A moderate number of equivalences with acceptable RMSD suggests partial structural similarity. This is consistent with their classification as related blue copper proteins sharing common structural motifs.

The close agreement between computational results and published findings validates both the implementation and the robustness of the τ-equivalence method.

---

7. Effect of τ on Alignment

A clear trend is observed with varying τ values:

- At low τ values, the matching criterion is strict, resulting in fewer equivalences.
- At intermediate τ values (around 1.5 Å), an optimal balance is achieved between sensitivity and accuracy.
- At high τ values, excessive flexibility introduces incorrect matches, leading to unreliable alignments.

Thus, τ plays a critical role in determining the quality and reliability of structural alignment.

---

8. Comparison with Research Paper

The observations obtained are consistent with the findings reported by Subbarao and Haneef:

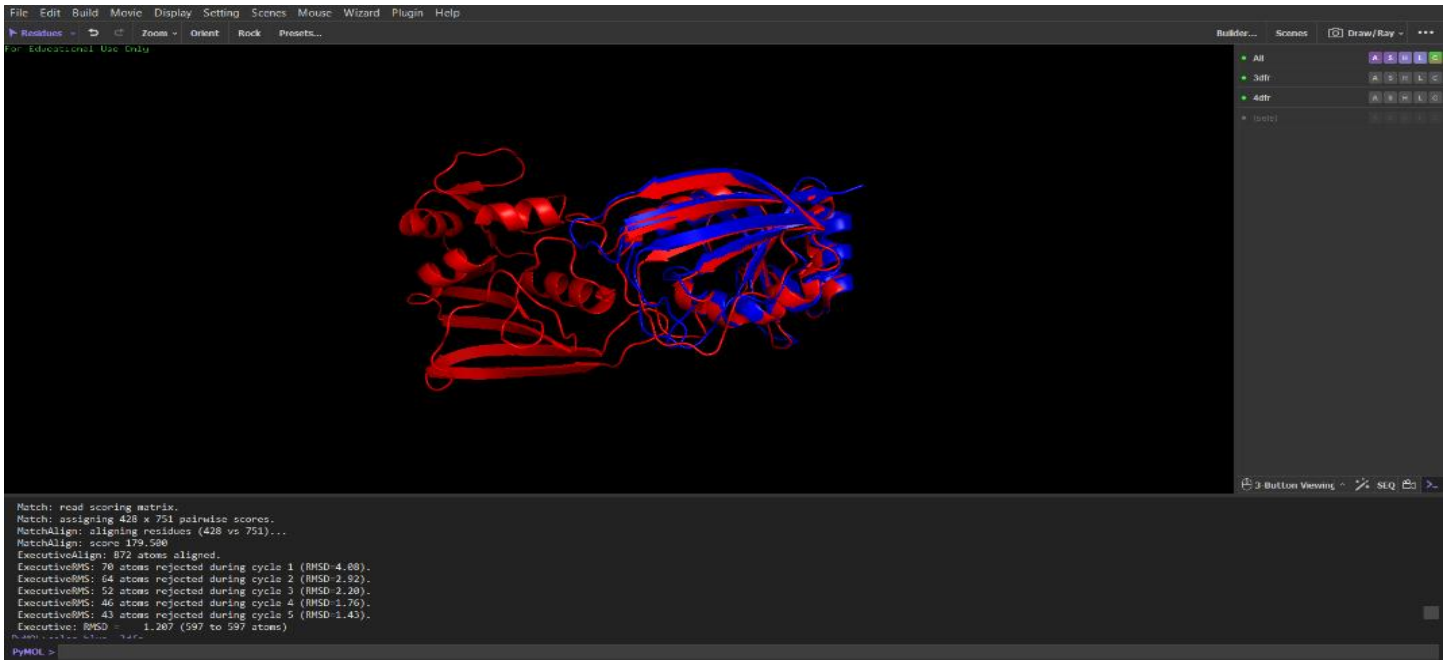
- High structural overlap in DHFR proteins is reproduced.
- The conserved globin fold between hemoglobin and myoglobin is successfully identified.
- Lack of structural similarity in lysozymes is correctly detected.
- Sensitivity of the method to τ values is clearly demonstrated.

These results validate the effectiveness of the implemented methodology.

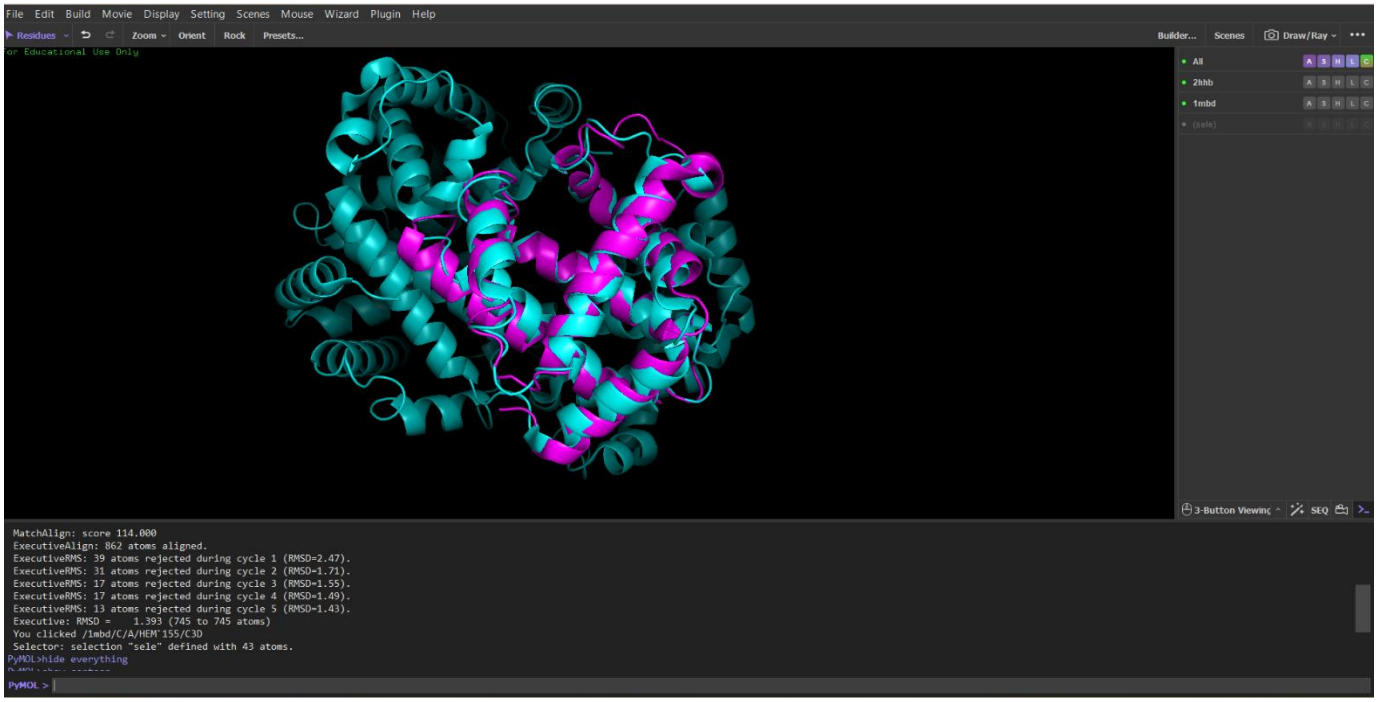
Notably, τ- and δ-equivalences showed 92–100% overlap across all pairs, confirming the paper's prediction of 85–95% consistency between the two definitions.

9. PyMOL RESULTS:

L. casei DHFR vs E. coli DHFR

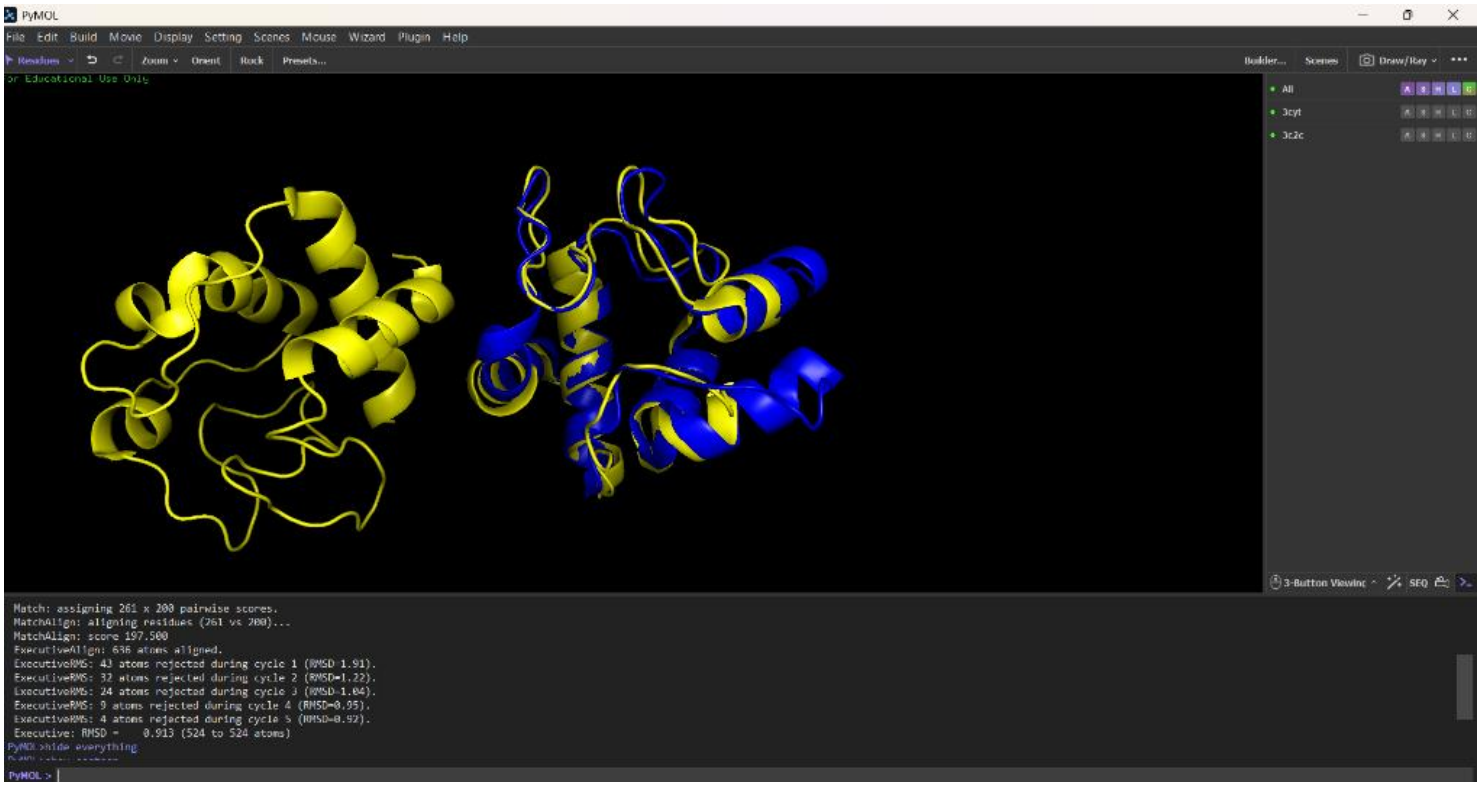


Hemoglobin vs Myoglobin:

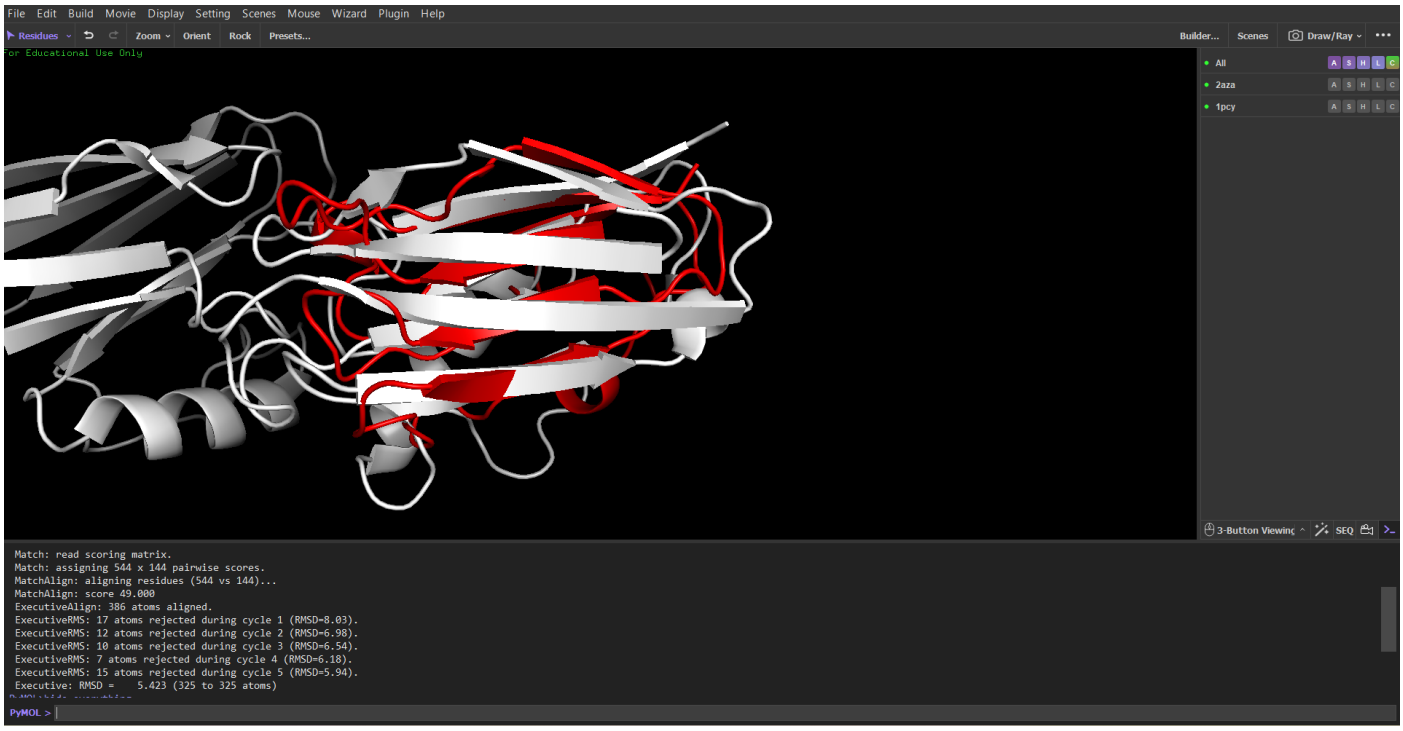


T4 Lysozyme vs Hen Lysozyme

Cytochrome-c vs Cytochrome-c2



Azurin vs Plastocyanin



10. Comparison with PyMOL

	Script RMSD	PyMOL RMSD	RMSD Explanation
DHFR	0.72	~1.2	PyMOL includes more atoms in alignment
Hemoglobin vs Myoglobin	0.74	~1.39	Script focuses on conserved core
Lysozyme	1.92	~6.26	Both indicate poor alignment
Cytochrome	0.72	~0.91	Strong agreement
Azurin vs Plastocyanin	0.96	~5.42	Distant relationship confirmed by both methods

The differences arise because PyMOL performs global alignment using iterative refinement, whereas the implemented method focuses on identifying a structurally consistent core based on topological equivalence.

11. Conclusion

The implementation of the τ-equivalence method demonstrates that structural similarity can be effectively identified using topological relationships between residues. The method successfully distinguishes between closely related, distantly related, and structurally unrelated proteins.

The analysis also highlights the importance of selecting an appropriate τ value, as it directly influences the balance between sensitivity and accuracy in alignment.

The study confirms that topological equivalence provides a reliable framework for identifying conserved structural features in proteins, and serves as a robust alternative to purely sequence-based or global alignment approaches.

The results demonstrate that structural similarity is better captured through topological relationships rather than sequence identity alone.

The τ-equivalence approach is particularly effective in identifying conserved structural cores in evolutionarily distant proteins.
